## Abstract

As synthetic biology moves away from “trial and error” and embraces more formal processes, workflows have emerged that extend from the conceptualisation of a genetic device to its construction and measurement. We are particularly interested in this latter aspect (i.e., characterisation and measurement of synthetic genetic devices), as this is a workflow component that has received relatively little attention, but is crucial to the success of such constructions. We present an end-to-end use case for engineering a basic synthetic construct, which is supported by information standards and computational methods, and which focuses on characterisation and measurement. This workflow captures the main stages of genetic circuit design and description, and offers standardised tools for both population-based measurement and single-cell analysis. The main contributions of the current paper are (1) Consideration of specific *vector features*. Although circuit design has been successfully automated, important structural information is usually overlooked, as is the case of plasmid vectors. We advocate the use of the Standard European Vector Architecture to select the optimal carrier for a design and a thorough description, in order to unequivocally correlate digital definitions and molecular devices. We developed a digital version of this plasmid format with the Synthetic Biology Open Language and a software

tool that allows the user to embed genetic parts in vector cargoes. This enables the annotation of a mathematical model of the circuit's kinetic reactions formatted with the Systems Biology Markup Language. From that point onwards the experimental results and their *in silico* counterparts proceed alongside, with constant feedback to preserve consistency between them; (2) A framework for the *calibration* of fluorescence-based measurements in synthetic biology. One of the hardest endeavours in standardisation, metrology, is addressed by reinterpreting the experimental output in light of simulation results, allowing us to turn arbitrary fluorescent units into relative measurements; (3) Integration of single-cell methods into a framework for *multicellular* simulation and measurement, allowing for standardised consideration of the interplay between the carrier chassis and culture conditions.

## Introduction

Synthetic biology is concerned with the rational design and construction of biological information processing devices.<sup>1</sup> The rigorous application of *engineering principles and processes* is fundamental to the success of this endeavour,<sup>2,3,4</sup> and significant attention is now being paid to the development of standardised *workflows*,<sup>5,6</sup> which describe sequences of biological and algorithmic processes required to obtain a desired outcome. Such workflows, therefore, specify a “tool-chain” for synthetic biology, and the anticipated benefits of using them include *modularity* (allowing individual processes to be implemented in several different ways), *robustness* and *scalability*.

One of the over-arching challenges for the field is the end-to-end *automation* of “biodesign”,<sup>7,8</sup> a process that is made up of two main stages:<sup>6</sup> (1) the automatic selection and/or construction of biological components, and their assembly into a network that, in principle, performs information processing according to a high-level specification, and (2) the fine-tuning of the system components and/or architecture to obtain the desired performance. The first part of this process concerns the detailed *specification* of the components to be used <sup>9,10</sup> (or fabricated <sup>11,12,13</sup>), the attendant data representation and storage issues,<sup>14</sup> and the correct arrangement of components into a *circuit* that can implement a given (logical) function. A wealth of so-called “bio-CAD” tools now exist for this latter task,<sup>15,16</sup> and these include SBROME,<sup>17,18</sup>

55 TinkerCell,[19](#) and SynBioSS.[20](#) In terms of “fine-tuning” (the second stage), recent  
56 developments use post-assembly modification of constructs based on observed network  
57 behaviour[6](#) or the “evolution” of cell models,[21](#) facilitating an iterative “homing in” approach  
58 towards circuit design.

59 In this paper, we focus on the latter stages of the circuit engineering process (that is, the  
60 implementation stages that follow the *initial* development of a circuit design). The *specific issues*  
61 that we address with our workflow (and, therefore, the most significant contributions of the paper)  
62 are (1) the formalisation of circuit description, (2) the effect of plasmid vectors on circuit  
63 performance, and (3) the correlation of experimental observations with simulation results. We  
64 now briefly discuss each of these.

65 The first stage in the post-design process is to formalise the descriptions and sequences of the  
66 parts of the system to be constructed. An early technical standard for the description of biological  
67 parts was the BioBrick,[22,23](#), which is appropriate for the assembly of DNA segments. However,  
68 a key consideration (which is not handled particularly well by early standards) is the variety of  
69 *plasmid vectors* that are available for the delivery of biological parts. Importantly, the choice of  
70 plasmid vector can dramatically affect the performance of an engineered circuit; plasmid features  
71 such as replication origin, selection markers and expression system need to be carefully  
72 selected.[24](#)

73 As computational tools to aid biodesign become more commonplace, we may begin to see more  
74 uniformity in terms of the types of circuit we see in the literature. However, once they are built,  
75 the process of *measuring* the behaviour of the designed system (in order to assess its fidelity to  
76 the desired output) may still vary substantially, since few existing workflows consider  
77 measurement, and teams are free to choose their own tools for this stage. Mathematical and  
78 computational modelling have become fundamental tools in synthetic biology, but they are only  
79 effective when combined with useful *in vivo* observations of synthetic systems. In this workflow,  
80 we describe a methodology for easily mapping simulation results onto laboratory measurements.

## Results and discussion

Our overall workflow is depicted in [1](#). We use a combined experimental *in vitro* / *in silico* approach, the two perspectives being tightly coupled at key points. The various stages are temporally ordered, from left to right, and we begin once a circuit design is established (that is, we do not consider issues of circuit design, and instead focus on implementation and measurement). The first stage in our workflow is *Description*, in which the design of the desired construct is captured by some representation(s); this then feeds into the *Implementation* stage, in which the construct is built (or modelled). Once the device has been implemented, we perform *Population-level measurement* in order to obtain aggregate performance metrics; this then feeds into a *second Implementation* phase, which facilitates closer (single-cell) observations. We now describe each workflow stage in more detail.

### Description

In order to obtain reliable and robust circuit performance, it is important to have control over the vector, and to be able to compare its performance with the same plasmid in multiple scenarios. In order to achieve this, we use (for the *in vivo* component) the Standard European Vector Architecture (SEVA)[25](#), which is a standard for the physical assembly of vector plasmids and their nomenclature, as well as an online database of functional sequences and constructs available to the community. Paired with the SEVA description of the *plasmid* is a digital representation of the *circuit* for the *in silico* component of the workflow, for which we use the Synthetic Biology Open Language (SBOL).[26](#) This provides a “standard exchange format” for synthetic biology designs (between research groups, and between different toolkits).

### Implementation

In the first *in vitro* Implementation phase, the vector is assembled using standard molecular biology procedures, resulting in the synthesis of circuit modules, and their insertion into the carrier plasmid. In parallel with this process (i.e., during the *in silico* implementation phase), we construct a standardised digital description using SBOL, with one SBOL document per

construction (File S2). These documents are then combined (using a Java-based tool, Tool S1), resulting in a single SBOL file containing the sequences of interest in the correct cargo position according to the restriction enzyme sequences. This tool identifies those SBOL components in common across components (i.e., the restriction sites) and replaces all the information that exists in the cargo section from enzyme to enzyme with the cassette of interest. After this step, both the plasmid containing the circuit and its representation are fully standardised.

## Measurements.

The use of mathematical modelling and computational analysis has become a fundamental part of synthetic biology, due to the information they provide concerning the mechanical behaviour of the systems. However, this potential can only be used effectively when combined with direct *in vivo* measurements.<sup>27</sup> Advances in metrology and measuring techniques will obviously benefit the field of synthetic biology. Recently, attempts have been made to standardise these. Relative Promoter Units (RPU)<sup>28</sup> have emerged as a measuring standard for promoter activity based on a comparison against a reference promoter. On a more abstract level, the Polymerase Operations Per Second (PoPs) measure<sup>9</sup> is used as the signal carrier in transcriptional circuits. However, none of these methods are free of controversy.<sup>15</sup>

In order to simulate the model constructed in the Implementation phase, we use the iBioSim<sup>29</sup> tool; conveniently, iBioSim exports reactions to a single Systems Biology Markup Language (SBML)<sup>30</sup> file (File S3), which is a computational standard for the representation of biochemical networks. Importantly, this allows us to link up the SBML *biochemical model* of the circuit with the SBOL description of the *DNA components* of the circuit, using the methodology described in.<sup>31</sup> In turn, this connects (via SBOL) with the SEVA description of the vector, giving seamless integration of information across different standards that are used for different levels of description. We also develop an application (Tool S2, based on libSBML<sup>32</sup>) to convert a given SBML file into Python coded scripts, used for for deterministic and stochastic simulations (File S4). Importantly, the SBML model details (i.e., rates) correspond not only to the circuit itself, but also its carrier vector. This significantly reduces output variability; by including details of the vector in the model characterisation (via SEVA/SBML) we take into consideration the possibility

135 that the carrier plasmid might later change, due to decisions taken at the implementation phase.  
136 Any such change will, in turn, inevitably (although, sometimes subtly) affect the observable  
137 behaviour of the model when implemented, so including details of the vector allows us to factor  
138 in fluctuations due to variable plasmid selection.

139 The inclusion of an extra step within the workflow for *multicellular* analysis will also help to  
140 reduce variability caused by both the chassis and culture conditions. Indeed, both chassis (i.e., *P.*  
141 *putida* vs. *E. coli*) and culture conditions add their own effects to the circuit and its carrier. If the  
142 circuit has to be used under different scenarios we should quantify cellular behaviour. In the  
143 example provided there are behaviours that cannot be measured with the cytometer (i.e., noise  
144 inheritance or cell movement), and which require time-lapse microscopy in order to be quantified.  
145 The parameters corresponding to these behaviours are therefore fitted according to single-cell  
146 measurements. Again, this information adds value to a potential specification sheet that  
147 accompanies the *in vivo* system.

148 We use spectrophotometry to measure the fluorescent signal of the entire cell population; dividing  
149 this by the optical density (OD) over time yields the average fluorescence value per cell in the  
150 culture. Experimental values are used to fit kinetic rate parameters in the mathematical models so  
151 they produce similar profiles. Importantly, in the graphs that follow, the Y-axis refers to *arbitrary*  
152 *units* of fluorescence in experimental observations, and the *number of molecules* (of, for example,  
153 mCherry proteins) in the simulated observations. Matching the latter with the former gives us an  
154 important reference point concerning measurements, which allows us to interpret subsequent  
155 results.

156 We perform stochastic analysis in order to characterise noise in the system, using the well  
157 established Gillespie algorithm.<sup>[33](#)</sup> On the experimental front, we obtain data on noise using flow  
158 cytometry, which allows the user to check the fluorescence intensity value of (in principle) every  
159 single cell in the bacterial culture. Although the ready-to-use graphs produced by the cytometer  
160 (Figure S1) are used as standard in most laboratories, we prefer to use the *raw values*, before they  
161 are processed for presentation (normally in a “black box” fashion, which is opaque to the user).  
162 There are three main reasons for using raw cytometry data: (1) Cytometers “count” cells using

163 variable intervals of fluorescence at high values of a logarithmic scale that is not always constant,  
164 and which depends on a specific machine set-up. This processing therefore introduces variability  
165 that is hidden from the user; (2) We need cell-specific values in order to make direct comparisons  
166 with simulated cells within our framework; (3) Raw data values are more amenable to importing  
167 and processing by various tool-chain components, whereas the automated extraction of specific  
168 values from graphs produced by cytometers introduces unnecessary complications and the  
169 possibility of misreading data.

170 A simulated cytometry graph is obtained by running the Python version of the reactions (see  
171 Methods). This offers two potential benefits: firstly, it gives a computational method (via an  
172 SBML model) of discarding invalid values from the raw cytometry information (see the later  
173 Case study for an example). And, secondly, by overlapping both experimental and simulated  
174 plots we are able to correlate the arbitrary units (*au*) of the cytometer with those from the  
175 spectrophotometer. We propose this procedure as one approach towards unifying machine-based  
176 measurements in the laboratory (and give an example in the Case study, below).

## 177 **Implementation (2)**

178 The behaviour of our circuit will inevitably be affected by the specific attributes of the host cell.  
179 A thorough characterisation of a device should, therefore, include information about the  
180 performance of the *chassis*[34](#) (which, in our case, is *P.putida* KT2440[35](#)). Rather than simply  
181 providing “added value”, this information is of *vital importance* in the case of multicellular  
182 applications,[36,37](#) which are becoming increasingly important as cell-to-cell communications are  
183 increasingly well-understood and customised.[38,39](#)

184 In order to study the behaviour of circuits *in vivo*, we use DiSCUS,[40](#) which is an agent-based  
185 simulation package we have previously developed to study bacterial growth. Importantly, this  
186 platform considers *physical forces* between rod-shaped bacteria, and is applicable to a wide range  
187 of organisms. This tool uses the previously generated Python scripts for the intra-cellular genetic  
188 network that is implemented by our cells. The SBML model is therefore embedded into the  
189 cellular objects of the agent-based simulator. It is important to note that there is a standard,

190 currently under development, called the Multi-Cellular Data Standard (MultiCellDS,  
191 <http://multicellds.org/>), which aims to create a data standard for sharing multicellular  
192 experimental, simulation, and clinical data. Hopefully, when released, it will facilitate sharing of  
193 configuration parameters for a specific chassis performance.

194 Concurrently, we prepare a 2-dimensional culture on an agarose pad,<sup>41</sup> and let the cells grow on  
195 a monolayer in order to facilitate visualisation in the microscope.

#### 196 **Single-cell measurements.**

197 We first calibrate the *movement and the growth* of the simulated cells according to experimental  
198 observations. We monitor the successive positions of a specific cell until division, and then  
199 follow the displacement of its daughters during their lifetime(s). We then match these results  
200 against the equivalent information obtained from the simulations, and adjust DiSCUS parameters  
201 to fit the experiments. In short (see Methods for more details), this information yields the most  
202 relevant features to prioritise in DiSCUS in order to reproduce the movement of our cells *in vivo*  
203 (in the Case study, below, we give specific examples).

#### 204 **Spatial measurements.**

205 After characterising the dynamics of the chassis that host our circuit, we measure its performance  
206 in a spatial scenario. We measure the fluorescence intensity of our device *in vivo*, and obtain a  
207 pixel-based image analysis of the specific colour (in our example, red) captured by the  
208 microscope. In our analysis, we translate the scale bar of the analysis into values proportional to  
209 those used in the mathematical model (see Methods for details of this conversion). As a  
210 consequence, a simulation run with the system's equations inside DiSCUS bodies, can be directly  
211 compared against experiments in regard to circuit function.

#### 212 **Case study**

213 In this Section we present the results of a combined *in vivo/in silico* case study, in which we  
214 construct a simple device using our workflow. We start with a simple “always-on” source; that is,

215 a constitutive expression cassette. Although this device is relatively simple, compared to existing  
216 synthetic genetic constructs (such as the oscillator), we emphasise that the main focus of the  
217 current paper lies with the *measurement* of such devices. That is, the complexity of the device to  
218 be constructed is less significant for the purposes of this work, as we are concerned only with  
219 handling its *output*. Fluorescence measurements are taken in fundamentally the same way,  
220 regardless of the size or complexity of a synthetic device; what interests us here is how we might  
221 *standardise* such metrics, and relate them back to *in silico* studies in a useful and meaningful way.

222 The two subcomponents of the circuit are (1) the *pEM7* constitutive promoter, and (2) the red  
223 fluorescence reporter gene *mCherry* (see Methods for details - File S1). Once the initial design is  
224 in place we move to the Description stage, where the system *pEM7-mCherry* is digitally  
225 formalised and physically built. The SEVA vector pSEVA 231 (Figure 2B) is selected to carry  
226 the design. This contains a Kanamycin marker (labelled 2), origin of replication pBBR1 (labelled  
227 3), and the default cargo sector (labelled 1). As the cargo sector is a sequence of restriction sites,  
228 we need to select specific locations into which to *paste* our modules. As depicted in Figure 2A,  
229 we complete the promoter component by flanking the sequences of restriction sites PacI and  
230 AvrII, and using HindIII and SpeI for the reporter gene (this leaves empty space in between for  
231 future usage). Once the Description phase is complete, we move to Implementation.

232 In Figure 3A we highlight the kinetic rates involved and the Ordinary Differential Equations  
233 (ODEs) that govern the continuous functioning of our always-on device. After cloning, Figure 4A  
234 shows the results for average fluorescence value per cell in the culture, along with deterministic  
235 simulation runs (based on the ODEs) for both the SBML model (implemented using iBioSim)  
236 and its corresponding Python script. We then move to the Population measurement phase.

237 Figure 4B shows the fluctuations in molecular levels of the reactions of Figure 3A when running  
238 the Gillespie algorithm on the SBML model (iBioSim) and its corresponding Python file. As  
239 expected, the observed variability is the same in both, as the kinetic rates remain unchanged (i.e.,  
240 the same as in the ODEs). The mean value is precisely situated on the steady state value of the  
241 deterministic simulation.

242 Raw data from the cytometer are plotted on Figure 4C, where the bimodal curve tells that  
243 approximately half of the cells display strong fluorescence, while the rest express none (or very  
244 little). The latter group corresponds to invalid values, and can be discarded, as indicated by the  
245 control data (the same strain without the plasmid) and the already processed graph (Figure S1).  
246 Moreover, further microscope tests show strong fluorescence in all the cells with a relatively  
247 narrow noise interval, which confirms the correct elimination of that non-expressing cell group.  
248 As described in the workflow description, this gives a computationally standard way of  
249 discarding invalid values from raw cytometry information. Moreover, it yields a method for  
250 correlating outputs from different pieces of laboratory equipment. We illustrate this in the graph  
251 of Figure 4C; we are able to correlate the arbitrary units (*au*) of the cytometer with those from the  
252 spectrophotometer: 1 *au* in the former, and  $\approx$  1.2 *au* in the latter (see Methods for more  
253 information). After performing population-level measurements, we move to single-cell  
254 measurements.

255 5A shows the result of experiments to track cell movements. 5B shows the positions of a cell  
256 (from Figure 5A) until division, and then the displacement of its daughters during their lifetime.  
257 5C shows the most relevant features we need to add in DiSCUS in order to reproduce the  
258 movement of our cells, starting from a very simple growth algorithm (which returns unrealistic  
259 patterns) (Figure 5C.1). Ultimately, we find that we need to include: (1) *cell size variations* (due  
260 to conditional growth), (2) variation in *transversal angles* after division, (3) *randomised*  
261 *directions of movement*, and (4) slight *attraction between cells* (in order to avoid the appearance  
262 of holes within the colony).

263 Figure 5D compares the synchrony of growth within experimental and simulated cells, yielding  
264 suggestions as to how to uncouple growth events. These graphs show the length of each cell in  
265 the population over *time* (in the laboratory experiments) or *iterations* (in the simulation). Starting  
266 with just two cells (the same setup as in 5A) which grow and divide at the same time, we observe  
267 that, after the second division (eight cells in total), the length of the cells is no longer  
268 synchronised.

269 We then consider the spatial scenario. Figure 6A shows the results of measuring the fluorescence

intensity of our *pEM7-mCherry* device inside the KT2440 strain, and a pixel-based image analysis of the red colour captured by the microscope. As stated above, the scale bar of the analysis is translated into values proportional to those in the mathematical model of [4b](#). A simulation run in DiSCUS, using the system's equations ([6B](#) (left)) can be directly compared against experiments. We verify, for instance, that daughter cells share output levels as they directly *copy* their mother's circuit at a given time ([6B](#)), and the fact that cells with slower growth tend to display a stronger light signal (due to the accumulation of fluorescence proteins).

## Discussion and conclusions

Arriving at a fully standardised workflow that allow for robust and reproducible constructs will benefit synthetic biology. We describe procedures used in our lab to build and measure synthetic devices, explaining both computational and experimental investigations via a simple use case. Many recent efforts focus on a specific step depending on application interests. That is the case of automated circuit design,[5,16,18](#) mathematical modelling,[20](#) single-cell analysis,[41](#) metrology,[28](#) data representation[26](#) or post-construction modification.[6](#) Indeed, there is significant room for improvement in each step along the workflow. However, instead of focussing on a single technique, we showed how to make use of *several* of them in an end-to-end workflow, concentrating on output measurements. There are recent reviews of other workflows,[15](#) but these tend to focus on enumeration rather than application of techniques. Apart from the *didactic* contribution of this paper, we provide new materials needed for linking standards, such as the tool to merge SBOL documents for SEVA description, or the scripts to translate SBML into Python. In this way, we provide a useful initial workflow for newcomers to the field, as well as (more generally) a standard workflow for robust programmable biology.

## Materials and Methods

**Strains and plasmids.** The strain used was *Pseudomonas putida* KT2440,[35](#) the wild-type strain derived from mt-242 strain cured of the TOL plasmid pWW0. The carrier plasmid for our circuit was pSEVA 231 (2: Kanamycin resistance; 3: pBBR1 origin of replication; 1: default cargo)

296 selected from the SEVA database (<http://seva.cnb.csic.es/>). We then inserted the promoter pEM7  
297 with *PacI/AvrII* and the mCherry reporter with *HindIII/SpeI*. The final plasmid was renamed  
298 pSEVA 237R-pEM7 (already available in the database). Importantly, the sequences of interest  
299 (target circuit) were edited to remove any restriction site that the SEVA standard uses as  
300 structural elements.

301 **SBOL-SEVA description.** The SEVA format is highly structured in unambiguous functional  
302 sectors, as shown in [2B](#). We described, using SBOL-2.0 (specifications on the website,  
303 <http://sbolstandard.org/>), the SEVA vector 231 (Figure S2). The previous existing description of  
304 this vector using GenBank format<sup>43</sup> is then improved by adding missing features (like assembly  
305 scars) and establishing structural and functional links. Separately, we produced two more SBOL  
306 documents, one for each component of the circuit. Ultimately, we developed a Java based  
307 application that can be fed with the carrier plasmid and the cassettes that needs to be inserted, and  
308 outputs the new vector. The application searches in the carrier file for those restriction sites  
309 present in the cassettes (iteratively) and substitutes the sequence in between. The resulting SBOL  
310 document has all location parameters (i.e. *bioStart*) updated.

311 **Mathematical modelling and SBML-to-Python conversion.** In the model of Figure [3A](#), *P* we  
312 show the promoter-reporter pair (18 copies, as estimated by previous observations for pBBR1  
313 origin of replication<sup>44</sup>), *mRNA* the messenger RNA and *rfp* the red fluorescent protein (both at 0  
314 molecules at the beginning of the simulation). Regarding the kinetic rates:  $k_1$  is the transcription  
315 rate ( $27/18 \text{ hour}^{-1}$ ,  $k_2$  represents the translation rate ( $2.5 \text{ hour}^{-1}$ ) and  $k_3$  ( $0.65 \text{ hour}^{-1}$ ) and  $k_4$  ( $0.265$   
316  $\text{hour}^{-1}$ ) the degradation rates of the mRNA and the protein respectively. For such a small network,  
317 parameter assignment is a difficult task due to the restricted number of constraints. Efforts on  
318 *assigning numbers* to rates<sup>45</sup> are of vital importance at this stage.

319 We then used the software iBioSim (<http://www.async.ece.utah.edu/iBioSim/>) to write the model  
320 in SBML format and run the simulations with the Hierarchical Runge-Kutta method for ODEs  
321 solution, and the Gillespie algorithm for stochastic behaviour. The model was exported in a *flat*  
322 (iBioSim option) XML file and converted into Python scripts with the tool provided (Tool S2).  
323 Flow cytometry data was obtained from the FCS files without processing, and the simulated

graph was obtained by (1) sampling a stochastic run in time (equal time intervals), and (2) counting intensity values over a long enough ( $\approx 600$  hours) period.

By making the simulations match experimental plots in Figure 4A, we conclude that  $\approx 400$  simulated molecules (s.m.) correspond to  $\approx 400$  arbitrary units in the spectrophotometer (a.u.s). As the computational measurements (s.m.) in the stochastic simulation are exactly the same, we used them to correlate the fluorescent units of the cytometer (a.u.c). As Figure 4C shows,  $\approx 400$  s.m. =  $\approx 330$  a.u.c; so  $1 \text{ a.u.s} = 400/330 \text{ a.u.c}$ . We assume that the sources of fluorescent signal are the same, as the cells are unaltered.

**Two-dimensional *in-vivo* setup.** In order to prepare of the microscope sample, we used an agarose pad following the method described in [46](#). A slide glass with an attached gene frame (1.7 X 2.8 cm, life technologies) was prepared. Then 500  $\mu\text{l}$  of LB, including 2% agarose, which is melted in the medium, was added into the middle of the gene frame and assembled with another slide glass. After 30 min at room temperature, one of the slide glasses was carefully removed, maintaining an intact agarose pad. Then, the pad was cut out to 5 mm width within the gene frame using a razor blade. Two strips of the pad were left to grow bacterial cells.

The strain carrying pSEVA 237R-pEM7 was precultured overnight in LB medium at  $37^\circ\text{C}$  and bacterial cultures were then diluted 100-fold in the same medium and grown to the exponential phase ( $\text{OD}_{600} = 0.2$ ). 2.5  $\mu\text{l}$  of the samples were then spotted on to the agarose pad and assembled with cover glasses (24 X 50 mm) for following microscopy analysis.

The widefield fluorescent microscope was used to observe the sample (Leica DMI6000B, Leica Microsystems) with a digital CCD camera Orca-R2 (Hamamatsu). The cell growth was monitored for 75 min under the microscope at  $37^\circ\text{C}$  and images were captured every 3 min with a 40.0x/0.75 NA dry objective or 63.0x/1.3 NA glycerol immersion objective (depending on the experiment) with a bandpass filter for mCherry (BP 560/40 and EM 645/75.) using the LAS AF v. 2.6.0 software (Leica Microsystems). Images were analyzed with the MATLAB-based code Schnitzcells<sup>47</sup> in order to track both the positions of the cells and their length while growing.

**Two-dimensional *in-silico* setup.** DiSCUS (<http://code.google.com/p/discus/>) is an agent-based software for bacterial growth that uses Pymunk (<http://pymunk.readthedocs.org/en/latest/>), a 2D physics library, to resolve collisions among cells. In the most basic test of Figure 5C.1 each cell is a body of 16x30 square lattice that grows lengthwise until division, when the cell is cut in half. Pressure-based growth is simulated by counting the cells that push a body of interest (threshold at 4 cells) and slowing down the growth events (without stopping them). Random angle variations were introduced after division, whereby the daughter cells *copy* the angle of the mother and add a number in the interval (-25,25) degrees. Furthermore, angle variations were included at the normal growth events, although to a smaller extent (maximum variation of 5 degrees). The fact that the cells grow *in vivo* forming a circular group without holes was simulated using a slight gravity-like value that pushed the cells towards the middle of the population. This force can be eliminated when the population is about 20 cells big, at which point the circular shape is conserved without any other attraction. Further analysis on this force is needed.

Regarding pixel intensity in the analysis of Figure 6A, we set the maximum value to be at the same level as the highest peak of the stochastic simulation of Figure 4B or the cytometry data of Figure 4C. Therefore we calculated the percentage rate ( $\approx 470 \cdot 100$  divided by maximum pixel value) to convert the intensity of every pixel into the scale shown by experiments. Again, we assume that the source of light is the same (KT2440) and variances are due to different machine measurements.

## 505 Figure Legends

506 Figure 1: **Workflow for an end-to-end synthetic biology use case.** The description that follows  
 507 (and modify) the design of an idea is the starting point for the consequent experimental and  
 508 computational methods. The circuit and its carrier vector are described using the SEVA (Standard  
 509 European Vector Architecture) format for the in-vivo workflow and the SBOL (Synthetic  
 510 Biology Open Language) standard for the parallel in-silico process. A first implementation round  
 511 is then performed via synthesis and cloning methods in the wet-lab and via SBML (Systems  
 512 Biology Markup Language) for the modelling. The resulting material is then used for different  
 513 measurements. First, we make use of usual laboratory equipment for population-based  
 514 experiments (spectrophotometry and flow cytometry) to compare the output against simulation  
 515 software (iBioSim and *ad hoc* python code). Another implementation round prepares the samples  
 516 for single-cell measurements. On the computational side, the SBML model is exported to a  
 517 python script ready to be used with our software for cell movement DiSCUS (Discrete  
 518 Simulation of Conjugation Using Springs). Relevant efforts are being currently done to  
 519 standardise these simulations via the MultiCellIDS (Multi Cellular Data Standard) project. On the  
 520 other side, the cells are grown on an agarose pad for 2-dimensional populations that allow us to  
 521 match results.

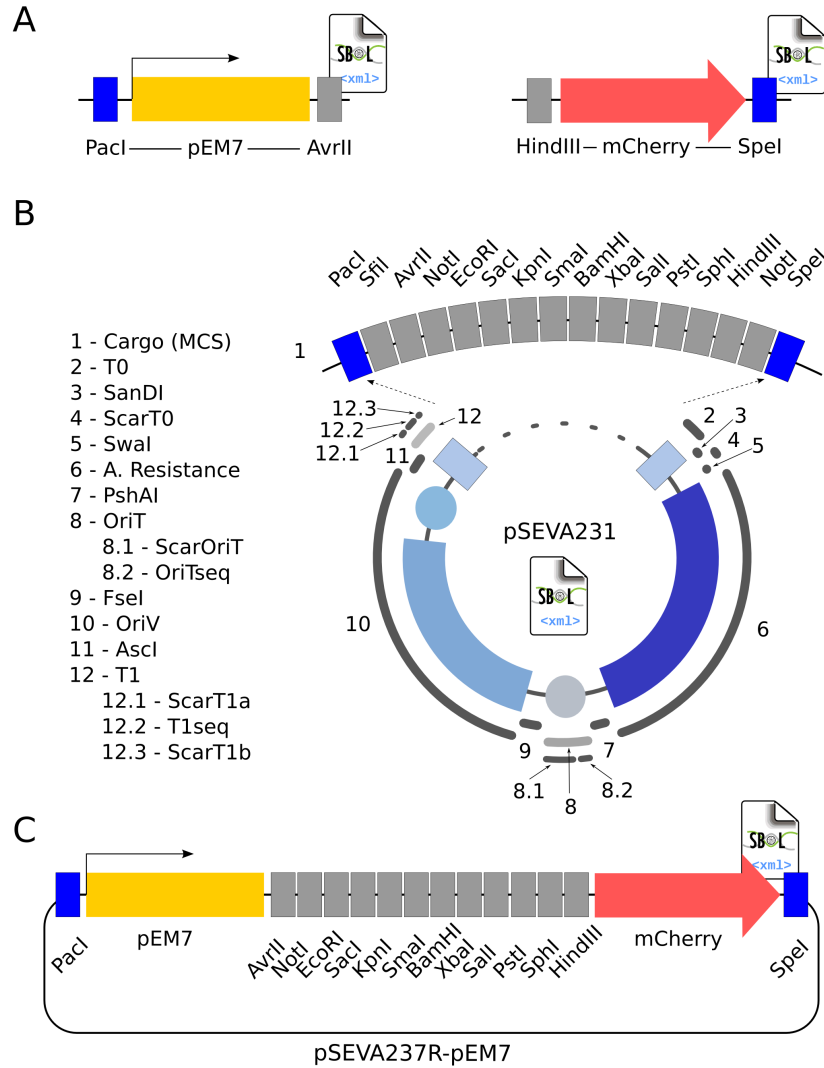

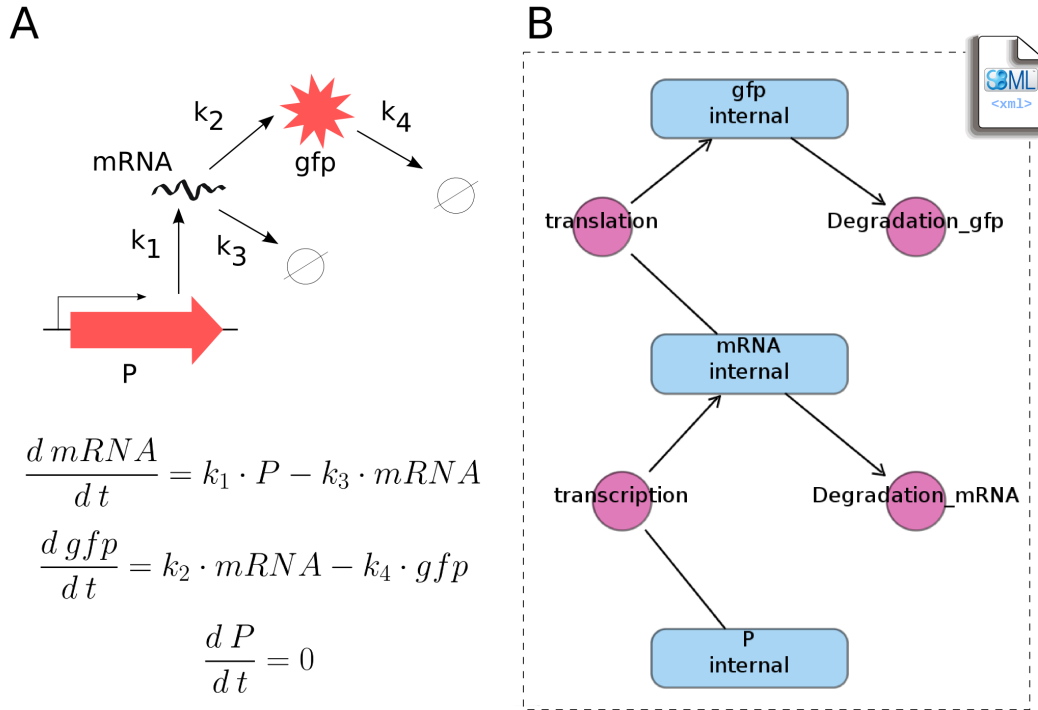

Figure 2: **SBOL description of circuit and SEVA components.** **A.** Circuit design modification where the components are flanked by the selected restriction sites that specify their situation inside the SEVA vector. The constitutive promoter pEM7 is surrounded by PacI and AvrII whereas the reporter mCherry is bordered by HindIII and SpeI. An SBOL document per component is created. **B.** The selected SEVA plasmid to harbour our circuit is SEVA number 231 (2: Kanamycin resistance; 3: pBBR1 origin of replication; 1: default cargo). All vector features are recorded in a single SBOL document, including cargo (multiple cloning site) components for a further assembling of circuit parts. **C.** Both in-vivo and in-silico protocols for building the final construct have the same basics: introduce, sequentially, circuit parts in the carrier vector. A software tool (Tool S1) allows to do so with SBOL documents.

532

533 **Figure3: Mathematical modelling and its SBML format** **A.** Kinetic reactions (up) and system's  
534 differential equations (bottom). The circuit's behaviour can be effectively simulated with just  
535 four kinetic constants: the constitutive promoter  $P$  facilitates reporter transcription with rate  $k_1$ ,  
536 resulting mRNA is translated with rate  $k_2$  leading to the formation of RFP (red fluorescent  
537 protein) and both elements are degraded with rates  $k_3$  and  $k_4$  respectively. ODEs (Ordinary  
538 Differential Equations) governing continuous dynamics are shown. **B.** Schema of the SBML  
539 model produced with the software iBioSim, a CAD (computer-aided design) package for systems  
540 biology. In the screenshot, blue elements represent substrates and red circles hide reaction rates.  
541 After setting the parameters, iBioSim allows the user to export the model to an XML file  
542 formatted following the SBML standard.

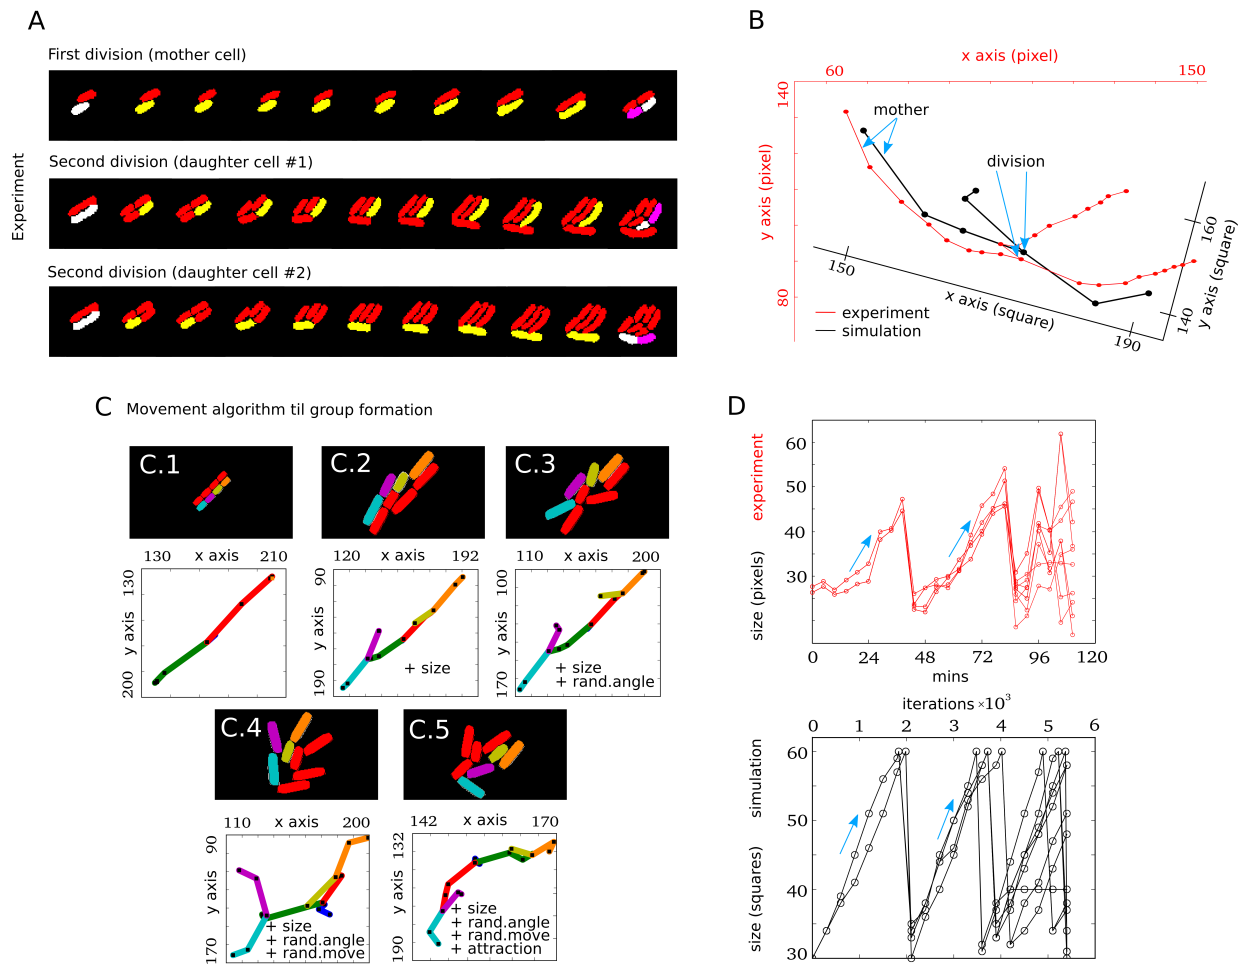

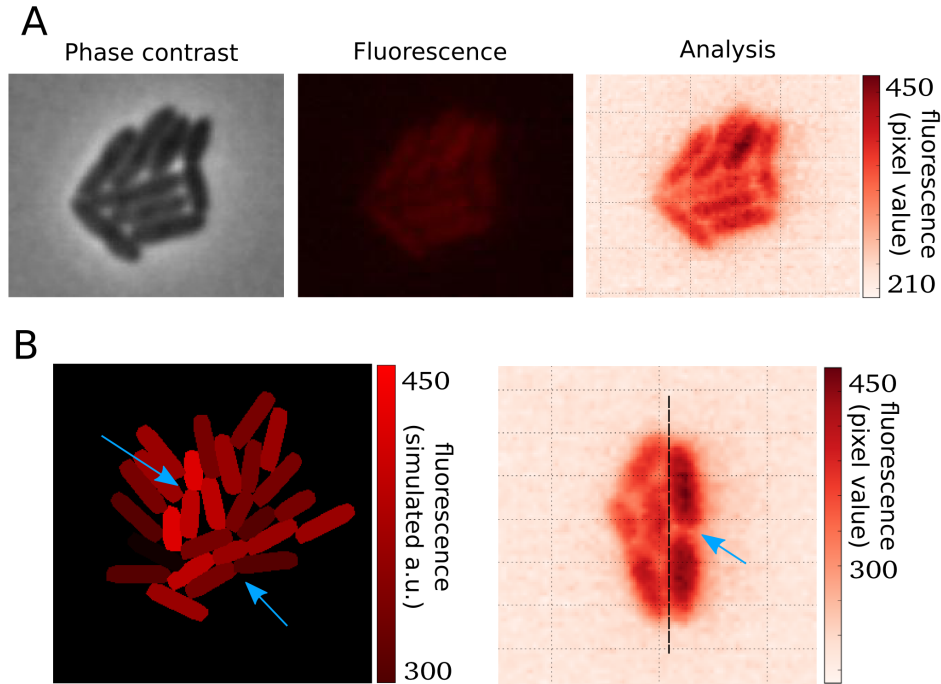

Figure 4: **Population-based measurements in experimental and simulation setups.** **A.** Deterministic functioning of the circuit, in terms of fluorescence intensity over time (during 14 hours), averaging the value of the whole population. Red line corresponds to experimental results, while blue and black lines show simulation runs of the model's differential equations with iBioSim and python code respectively. Experimental values are used to fit rate numbers in mathematical models so they produce similar continuous lines. **B.** Stochastic behaviour of the system according to simulations. The blue line results of running the Gillespie algorithm with iBioSim whereas the black line shows the python script behaviour. As expected (same algorithm with equal parameters), the fluctuations are alike. **C** Fluorescence intensity values of each cell in the population measures variability and expression noise. Experimental raw data extracted by flow cytometry (without processing by the cytometer, see text for details) corresponds to the red line. Black line results from counting expression values in the simulation with the python script, while grey area represents the control (plasmid-free cells) measured experimentally. Note that scales are different in simulation and experimental lines, standing for variability within arbitrary units (a.u.).

**Figure 5: Characterisation of chassis mechanics.** **A.** Tracking cell lineages in a experimental setup. Starting from the division of a single cell (up) we follow the movement of its daughters (middle and bottom) in order to define their movement behaviour until next division. **B.** Position coordinates are recorded during the experiment (red line) and simulation (black line) to fit parameters by comparing both outputs. Cell traces are overlapped for visualisation purposes and axis rotated accordingly to show dimensions. **C.** Parameter estimation for cell movement. Different features are included, sequentially, in order to get the final moving procedure for in-silico simulations. Starting from inaccurate movement (C.1) we add size variability due to pressure (C.2), random angles after division (C.3), irregular motion changes (C.4) and slight cell attraction to simulate viscous bodies (C.5). All simulations start from a single cell, and one lineage is coloured to monitor coordinate positions. **D.** Synchrony of cell growth. The length of

570 each cell (y axis) is monitored over time (x axis) in both scenarios (experiment, up; simulation,  
571 bottom). The initial cells grow at the same time until division point is reached, whereas the third  
572 generation of cells grow asynchronously.

573 Figure 6: **Spatial progress of the genetic device.** **A.** Phase contrast image of population (left),  
 574 fluorescent picture (middle) and computational analysis (right). In the latter, the colour scheme  
 575 (right bar) represents the value of the red channel of every pixel from 0 to 255. However it is  
 576 transformed into a [0..450] scale in order to allow comparisons with previous fluorescence  
 577 measurements. **B.** On the left, we show a simulation of a colony starting from a single cell.  
 578 Upper-left arrow highlights cells with slower growth rate and RFP accumulation while bottom-  
 579 right arrow points at a recently divided cell where both daughters share similar RFP  
 580 concentration. On the right, expression noise inheritance is indicated with an arrow. Furthermore,  
 581 RFP accumulation caused by slow growth can be observed by the black line separation: a single  
 582 cell started from each side.
